1. Introduction

Figure 1 Overview of neutral atomic and molecular cooling and trapping. The energy scale spans 12 orders of magnitude in kinetic energy E of atomic motion, expressed in temperature units $T = E/k_B$ (k_B is the Boltzmann constant). The length scale shows the corresponding de Broglie wavelength $\lambda = h/p$ (h is the Planck constant), where momentum $p = (2mE)^{1/2}$. The line to guide the eye is calculated using the mass of the ^{23}Na atom for m . Typical atomic dimensions are on the order of $1a_0 = 0.0529\text{nm}$, the Bohr radius of the H atom, whereas Bose–Einstein condensates can have dimensions on the order of $100\text{ }\mu\text{m}$. The figure also indicates typical orders of magnitude for familiar energy scales associated with atomic fine structure, hyperfine structure, natural radiative broadening and optical or magnetic energy shifts. Cooling requires a dissipative process to remove kinetic energy, whereas trapping requires a spatially dependent force to act on the atoms. Laser cooling^{2,4} typically reaches kinetic energies below 1 mK , where $k_B T$ is smaller than natural line widths, and atoms can be confined in a magneto-optical trap or optical trap. The latter uses a spatially dependent light shift attributable to a laser field to create a trapping potential for atoms. Similarly, a standing-wave light field can produce a periodic potential in space called an optical lattice^{5,6} with individual lattice cells spaced by ... $\lambda/2$, where λ is the wavelength of the laser that makes the lattice. Atoms whose magnetic Zeeman shift decreases with decreasing field strength can be trapped in a region of space with a magnetic field minimum. Evaporative cooling⁵ of trapped atoms can dramatically lower the temperature and reach the limit of quantum degeneracy, where the phase space density ρ , defined as the number of particles per cubic thermal de Broglie wavelength, is of order unity. If the atoms are bosons, then Bose–Einstein condensation occurs when ρ reaches the critical value of 2.6 (ref. 6; and see review in this issue by Anglin and Ketterle, pages 211–218).

Large condensates and interference patterns

Wolfgang Ketterle came to the Massachusetts Institute of Technology (MIT) in 1990. He worked with a different alkali atom, sodium, and published his BEC results four months after Cornell and Wieman, but with a condensate containing some hundreds of times more atoms. In an interference experiment he showed that all the atoms really were linked in a single wave of

and then causing these to expand into each other, he could observe distinct interference patterns – rather like what happens when two stones are thrown into still water at the same time. The interference pattern would not have formed unless the matter waves were coherent.

Many-body Hamiltonian

$$H = \int d\mathbf{r} \, \psi^\dagger(\mathbf{r}) \left[-\frac{\hbar^2}{2m} \nabla^2 + V_{\text{ext}}(\mathbf{r}) \right] \psi(\mathbf{r}) + \frac{1}{2} \int d\mathbf{r} d\mathbf{r}' \, \psi^\dagger(\mathbf{r}) \psi^\dagger(\mathbf{r}') V(\mathbf{r} - \mathbf{r}') \psi(\mathbf{r}') \psi(\mathbf{r})$$

The mean field theory

$$\psi(\mathbf{r}, t) \approx \langle \psi \rangle + \delta\psi(\mathbf{r}, t)$$

Gross-Pitaevskii equation

$$i\hbar \frac{\partial \psi}{\partial t} = \left[-\frac{\hbar^2}{2m} \nabla^2 + V_{\text{ext}}(\mathbf{r}) + g |\psi|^2 \right] \psi$$

Gross-Pitaevskii equation

$$i\hbar \frac{\partial}{\partial t} \psi(r,t) = \left[\frac{\hbar^2}{2m} \nabla^2 + V_{\text{ext}}(r) + \frac{4\pi\hbar^2 a}{m} |\psi(r,t)|^2 \right] \psi(r,t)$$

Long time solution

$$\psi(x,t) = \frac{1}{\sqrt{t}} e^{i\frac{x^2}{2t}} \left| \psi\left(\frac{x}{t}\right) \right|^{\log(4t)} O(t^{-1} \log t)$$

$$\left| \psi(k) \right|^2 = \frac{1}{2g} \log(1 + |r(k)|^2)$$

Theoretical explanation

Fringe position

$$k_n = 2\sqrt{E_n} = 2\sqrt{V_0} + n\frac{1}{2}\sqrt{2V_0}^{1/2}$$

Central fringe

$$k_0 = k_1 = k_1 = 4\sqrt{V_0/2}^{1/2}$$

FIG. 1. Evolution of two BECs ($g = 2, d_0 = 12, \sigma = 1$). The scaled packets at (a) $t = 3$, (b) $t = 9$, and (c) $t = 54$. (d) $|\alpha(k)|^2$ in Eq. (4).

Experimental prediction:

1. Energy level
2. Many wave packets

FIG. 2. The potentials, the energy levels, and the levels in k . Two Gaussian wave packets with (a) small separation, (b) large separation, and (c) three Gaussian wave packets. The solid level lines are accurate numerical results while the dotted lines are analytical results for comparison. Note that the energy levels in (b) are magnified by a factor of 10; the k level spacing is the fringe spacing at the interference band in the main text.

Ratio of level width to level spacing

$$\frac{k_n}{k_n} = \frac{E_n}{E_n} = 2 e^{2 \sqrt{g} E_n w} E_n$$

5.0 ms

5.8 ms

6.0 ms

Fig. 6. AC Josephson effect in optical lattices, as observed through the interference profile of atoms suddenly released from a vertically confined, one-dimensional optical lattice. The relative phase ϕ between adjacent wells evolves according to the Josephson relation $(\hbar/\2\pi)(d\phi/dt) = V$, where $\hbar$ is Planck's constant, t is time, and V is the chemical potential difference between adjacent wells. This evolution results in an oscillation of the populations of diffraction orders in the interference signal. In this work, V is determined by gravity. The time label references the time interval that the atoms were held in the combined gravitational plus optical lattice potential. The color scale on the right indicates the intensity of the interference pattern.

Quantum tunneling

Temperature dependence

$$I(T) = I_0 \left(1 + e^{\frac{\hbar \omega_0}{k_B T}} \right) e^{-\frac{432 V_{\max}}{\hbar \omega_0}} e^{-\frac{\hbar \omega_0}{k_B T}}$$

At high temperature:

Arrhenius law

$$I_{AR} = \frac{I_0}{2} e^{-V_{\max} / k_B T}$$

At intermediate temperature:
Thermally assisted tunneling

$$T_{cr} = \frac{hw_0}{2 k_B}$$

Crossover temperature

$$T_{cr} = 257 nK$$

$$U_l(x, y) = 2.1 E_R$$

At low temperature:
Pure quantum tunneling

FIG. 1. The temperature dependence of the decay rate $\Gamma(T)$ for ^{87}Rb atoms with Yale experimental parameters $\lambda = 850$ nm, $U_l(x, y) = 2.1E_R$, where $E_R = \frac{2\pi^2 \hbar^2}{m\lambda^2}$ is the recoil energy.

2.3. Soliton

L. Khaykovich et al., Science 296, 1290 (2002).

Fig. 1. Experimental setup for soliton production. ^7Li atoms are evaporatively cooled in a Ioffe-Pritchard magnetic trap and transferred into a crossed optical dipole trap in state $|F = 1, m_F = 1\rangle$ where they Bose condense. Magnetic tuning of the scattering length to positive, zero, and negative values is performed with the two pinch coils (PC). Switching-off the vertical trapping beam (VB) allows propagation of a soliton in the horizontal 1D waveguide (HB). Absorption images at different times after release are recorded on a charge-coupled device camera in the x, z plane.

Fig. 3. Absorption images at variable delays after switching off the vertical trapping beam. Propagation of an ideal Bose-Einstein gas (A) and of a soliton (B) in the horizontal 1D waveguide in the presence of an expulsive potential. Propagation without dispersion over 1.1 mm is a clear signature of a soliton. Corresponding axial profiles are integrated over the axial direction.

2.4. Vortex and Abrikosov lattices

J. R. Abo-Shaeer et al., Science 292, 476 (2001).

FIG. 11. Condensate images showing the first BEC vortex and the measurement of its phase as a function of azimuthal angle: (a) condensate image before being put in that state in a way that forms a vortex; (b) the same state after a $\pi/2$ phase has been applied that produces a vortex; (c) the same state after a 2π phase has been applied that produces a vortex; (d) residual phase difference between the states in (a) and (b); (e) radial average of the phase difference calculated in (d). The data are repeated after the azimuthal angle 2π to better show the continuity around the ring. This shows that the phase winding corresponds to a quantized angular momentum. From Matthews et al., 1999a. [Color].

Superfluidity

L. Pitaevskii et al., Science 298, 2144 (2002).

Figure 4 Signature of superfluidity in a Bose-condensed cloud⁶³. The condensate and its thermal 'halo' of normal gas respond differently when they are dragged through a periodic potential. In the experiment, the clouds were displaced in a magnetic trap superimposed by an optical lattice. The condensate, distinguished by its much higher

density (colour coded in red), tunneled through the potential peaks and oscillated in the magnetic trapping potential, whereas the normal fraction was pinned by the optical lattice. Interaction between the two clouds eventually led to damping of the condensate motion.

3. Quantum phase transition

Superfluid

Mott insulator

Insulator + disorder = Bose glass

Insulator + weak disorder = Anderson glass

Berezinskii–Kosterlitz–Thouless transition

Cold atoms in optical lattices. (Top) Cold atoms in a periodic optical potential localize near the potential minima. The atoms can tunnel to neighboring sites with hopping amplitude J . Atoms on the same site repel each other according to the onsite interaction U . For weak lattices ($J \gg U$), the atoms form a superfluid (BEC) with atoms delocalized over many lattice sites. With increasing laser intensity ($J \ll U$), the atoms form a Mott insulator state in which atoms are locked at individual lattice sites (3). (Bottom) Experimental signatures of the superfluid–Mott insulator transition (4). In the superfluid (rear), the atoms show an interference pattern, which disappears in the Mott phase (front). (Right) Entangling atoms in a lattice. Depending on their internal state, atoms collide with neighboring atoms when the potential holding atoms in one state is moved while the potential holding atoms in the other state is kept stationary (11, 12).

C.E. Wieman, Nature 412, 295 (2001).

Figure 3 A burst focus. **a**, Conceptual illustration of a radial burst focus. t_{burst} is the time at which the burst is generated and T_{rad} is the radial trap period. **b**, An image of a radial burst focus taken 33.5 ms after a jump from $a_{\text{int}} = 0$ to $-30a_0$ for $N_0 = 10,000$. $T_{\text{rad}}/2 = 28.6$ ms, which indicates that the burst occurred 4.9(5) ms after the jump. The axial energy distribution for this burst corresponded to an effective temperature of 62 nK. The image is $60 \times 310 \mu\text{m}$. **c**, Radially averaged cross-section of **b** with a gaussian fit to the burst energy distribution. The central 100 μm were excluded from the fit to avoid distortion in the fit due to the condensate remnant ($\sigma = 9 \mu\text{m}$) and the thermal cloud ($\sigma = 1.7 \mu\text{m}$). The latter is present in the pre-collapse sample due to the finite temperature, and appears to be unaffected by the collapse. The dashed line indicates the fit to this initial thermal component. We note the offset between the centres of the burst and the remnant. This offset varies from shot to shot by an amount comparable to the offset shown.

6.2. Collapse of Fermi gas

M. Inguscio, Science 297, 2240 (2001).

Fig. 2. False-color reconstruction of the density distribution of the Fermi (front) and Bose (back) gases during the evaporation procedure, as detected after a ballistic expansion of 4 ms for K and 9 ms for Rb. (Left) the BEC starts to form at the center of the cloud and is coexisting with a relatively large Fermi gas; (middle) as the BEC grows larger, the Fermi gas is only moderately depleted; (right) when a quasi-pure condensate of 10^5 atoms has formed, the Fermi gas has already collapsed. The fermionic distributions have been vertically expanded by a factor of 3.

9.3. Superflow in Solid Helium

M. Chan, Science 305, 1941 (2004).

Fig. 1. Torsional oscillators: The cylindrical drive and detection electrodes are coupled capacitively to the two planar electrodes attached as fins on the two sides of the cylindrical torsion cell. Oscillation of the torsion cell induces a voltage in the detection electrode. This voltage enables a lock-in amplifier to keep the oscillation in resonance. The outside diameter, width, and height of the torsion cell are 15 mm, 1.1 mm, and 5 mm, respectively.

10.3. Atom interferometer (microgravity)

M. A. Kasevich, Science 298, 1363 (2002)

10.3. Interferometer

J. Denschlag et al., Science 287, 97 (2000).

Fig. 1. (A) Writing a phase step onto the condensate. A far-detuned uniform light pulse projects a mask (a razor blade) onto the condensate. Because of the light shift, this imprints a phase distribution that is proportional to the light intensity distribution. A lens (not shown) is used to image the razor blade onto the condensate. The mask in (B) writes a phase stripe onto the condensate. The mask in (C) imprints an azimuthally varying phase pattern that can be used to create vortices.

10.4. Waveguides

Science 298, 1363 (2002)

Fig. 3. Schematic of a possible geometry for a waveguide Sagnac-effect atom gyroscope. An atom gain element (blue) feeds a loop waveguide structure (red). Atoms are extracted and detected using correlated-state techniques to achieve sub-shot-noise limited detection (yellow). The past year has seen substantial progress in the development of each relevant element. A loop 10 cm by 10 cm might achieve a 10^6 -fold improvement in sensitivity to rotations for intermediate acquisition bandwidths (tens of seconds), and a 10^4 -fold improvement for high frequencies (less than 1 s). The long-term stability and accuracy are difficult to project.

10.5. BEC on chip Nature 413, 498 (2001).

Figure 1 The chip and the magnetic potentials that it creates. **a**, Layout of the lithographic gold wires on the substrate. The inset shows the relevant part of the conductor pattern. I_0 , I_1 , I_{M1} and I_{M2} create the various magnetic potentials for trapping (see **b**) and transport, as described in the main text, I_0 is used only during trap loading (intermediate MOT step⁵). **b**, Potentials created by a wire current $I_w = 2$ A for two different values of the external

FIG. 1. A quantum dot (tweezer) moving through a BEC (reservoir) with the speed of v . The diagram illustrates that a resonance occurs as the dot moves further from the trap center such that the energy of the dot matches the chemical potential μ of the condensate. If one of the atoms is lost from the dot, the energy level of the lost atom is lowered, and it is lost to the condensate at this position.

10.7. Information storage

C. Liu et al., Nature 409, 490 (2001).

10.8. Quantum computer and entanglement

Nature 409, 63 (2001).

Figure 1 Reduction in the squeezing parameter ξ^2 . A fast $\pi/2$ pulse between two internal states is applied to all atoms in the condensate. The subsequent free evolution with time results in a strong squeezing of the total spin. The angle θ is chosen such that ξ_θ^2 is minimal. The solid line shows the results of a numerical integration (see text). For numerical convenience we have assumed a spherically symmetric potential $V(r) = m\omega^2 r^2/2$. The parameters are $a_{ss}/d_0 = 6 \times 10^{-3}$, $a_{sb} = 2a_{ss} = a_{ss}$, and $N = 10^6$. The dashed curve shows the squeezing obtained from the hamiltonian $H_{\text{spin}} = \hbar\chi J_x^2$. The parameter χ is chosen such that the reduction of $\langle J_x \rangle$ obtained from the solution in ref. 7 is consistent with the results of ref. 11.

10.9. Four-wave mixing

L. Deng et al., Nature 398, 218 (1999).

a Lab frame:

b Moving frame:

$$\vec{V} = \frac{\hbar k}{M} \hat{x}$$

Figure 1 Momentum-energy conservation for 4WM and the bosonic stimulation viewpoint in a moving frame. **a**, Momentum conservation, $\vec{P}_4 = \vec{P}_1 - \vec{P}_2 + \vec{P}_3$ (equivalent to phase-matching in optical 4WM), in the laboratory frame. For clarity, over-arrows indicate vectors. Energy conservation requires $P_4^2 = P_1^2 - P_2^2 + P_3^2$. **b**, It is always possible to view matter 4WM in a frame moving with velocity $\mathbf{v}$ such that the three input momenta have the same magnitude, and two are counter-propagating. Then, in our case two atoms in momentum states $\vec{P}'_1 = -\hbar k \hat{x}$ and $\vec{P}'_3 = \hbar k \hat{x}$ are bosonically stimulated by wavepacket $\vec{P}'_2 = \hbar k \hat{y}$ to scatter into momentum states $\vec{P}'_2$ and $\vec{P}'_4 = -\vec{P}'_2 = -\hbar k \hat{y}$. (We note that the energy and momentum conditions are satisfied independently of the direction of $\vec{P}'_2$. The 4WM wavepacket is a consequence of energy, momentum and particle-number conservation while atoms are stimulated into the momentum state $\vec{P}'_2$. Thus 4WM can be viewed as the annihilation of momentum states $\vec{P}'_1$ and $\vec{P}'_3$, and the creation of momentum states $\vec{P}'_2$ and $\vec{P}'_4$ (the minus signs in the energy and momentum conditions are attached to the state that gains atoms). It is this bosonic stimulation of scattering that mimics the stimulated emission of photons from an optical nonlinear medium. Alternatively, by choosing a frame of reference in which $\vec{P}'_1 = -\vec{P}'_2$ (or $\vec{P}'_2 = -\vec{P}'_3$), 4WM can also be viewed as matter-wave Bragg diffraction of $\vec{P}'_3$ ($\vec{P}'_1$) from the grating produced by the interference of two others.
